

PRODUCTION OF GREASE FROM USED LUBRICANT: A FEASIBILITY STUDY

NABIL FIKRI BIN YAAKUB

**A report submitted in partial fulfillment of the
Requirement for the reward of the degree of
Bachelor of Chemical Engineering**

**Faculty of Chemical Engineering and Natural Resources
University Malaysia Pahang**

MAY 2008

I declare that this thesis entitle “*Production of Grease from Used Lubricant*”
Is the result of my own research except as cited in the references. The thesis
has not been accepted for any degree and is not concurrently submitted
in candidature of any other degree.

Signature:

Name of Candidate: Nabil Fikri bin Yaakub

Date: 18 MAY 2008

Special Dedication of This Grateful Feeling to My...

Beloved mother;

Pn. Koret Bt Md Lim

Supportive Lecturer

Prof. Dr Rosli Mohd. Yunus, Mr. Zulkifli Jemaat, Ms Noralisa,

Ms. Mazni, Mr Maryudi

My Beloved Friends

Khairul Rahimi Kamam, Mohamad Saifuddin Idris, Mohd. Zaffaruddin Mohamad

Mohd Fauzi Ramlam, Khairul Afifi Abu Bakar, Mohd. Izzuddin, Abd. Hakim Abadi

Mohd. Munzir Hamzah and Mohd. Khairul Yaacub.

For Their Love, Support and Best Wishes.

ACKNOWLEDGEMENT

First and foremost, I wish to express my sincere appreciation to my main thesis supervisor, Prof Rosli b. Mohd Yunus and Mr. Zulkifli Jemaat for constantly guiding and encouraging me throughout this study. Thanks a lot for giving me a professional training, advice and suggestion to bring this thesis to its final form. Without their support and interest, this thesis would not have been the same as present here.

Secondly, we would like to extend my word of appreciation to PM. Dr. Sharifah Aishah Syed Abd Kadir and to all staff from Department of Chemical Engineering, Universiti Teknologi Mara Shah Alam for their profession training, advice and suggestion in preparing this thesis.

In particular, my sincere thankful is also extend to all my colleagues and others who have provide assistance at various. Their views and tips are useful indeed. Unfortunately, it is not possible to list all of them in this limited space. And last, but not least I thank my family members for their continuous support while completing this thesis.

ABSTRACT

Grease is a mixture of a fluid lubricant usually petroleum oil and a thickener (soap) dispersed in the oil. The base oil (petroleum) can be changed by using the used lubricant. Other than base oil, thickener may play an important role in the mixture. Soap thickeners are formed by reacting metallic hydroxide, or alkali, with a fat, fatty acid, or ester. Since the petroleum prices were increased each year, using used lubricant as base oil is the best solution to produce grease in the low cost at the same time it will decrease the water pollution. Three types of soap are used in this production that is aluminum soap, calcium soap and sodium soap. Viscometer was used in this experiment to analyze the quality and performances of grease product to select the best type of soap to produce grease. The viscosities of grease are tested by changing the spindle speed for each type of soap. The different percent of soap are used to know the effect of percent of soap to the viscosity of grease. In this experiment, grease was successfully produced from used lubricant. The viscometer test and sample preparation on grease was visualized in this research, where the viscosity of grease was decreased with the increasing of spindle speed and the viscosity was increased with the increasing of percentage soap (thickener) added. The best way to produce grease is with sodium soap, where sodium soap is the strongest thickener compared to another thickener. Using this type of soap, only a small amount of this thickener is needed compared to another type of soap.

ABSTRAK

Gris ialah campuran cecair pelincir kebiasaannya minyak petroleum dan agen pengental (sabun) kemudian dilarutkan ke dalam minyak. Minyak petroleum boleh digantikan dengan minyak pelincir terpakai. Selain daripada minyak petroleum, agen pengental memainkan peranan yang penting di dalam campuran tersebut. Agen pengental dihasilkan melalui tindakbalas logam hidroksida, atau alkali dengan lemak, asid lemak atau ester. Memandangkan harga petroleum meningkat sejak kebelakangan ini, pilihan terbaik adalah dengan menggunakan minyak pelincir terpakai sebagai pengganti kepada minyak petroleum, ia bukan sahaja dapat mengurangkan kos pengeluaran gris malahan dapat mengurangkan pencemaran air yang berpunca daripada pembuangan minyak pelincir terpakai ke dalam sungai. Tiga jenis sabun pengental yang digunakan dalam penghasilan gris dalam kajian ini adalah sabun aluminium, sabun kalsium dan sabun natrium. Viskometer digunakan didalam kajian ini untuk menganalisis kualiti dan prestasi gris untuk pemilihan sabun pengental terbaik dalam penghasilan gris. Kelikatan gris tersebut dikaji dengan mengubah kelajuan pemutar untuk setiap jenis sabun pengental. Perbezaan peratusan sabun pengental juga disukat kelikatannya untuk mengkaji kesan kuantiti sabun pengental kepada kelikatan gris tersebut. Didalam kajian ini gris telah berjaya dihasilkan dengan menggunakan minyak pelincir terpakai menggantikan minyak petroleum. Penghasilan gris dan analisis kelikatan telah direalisasikan didalam kajian ini, yang mana kelikatan gris berkurang dengan pertambahan kelajuan pemutar dan bertambah dengan pertambahan kuantiti sabun pengental. Cara yang terbaik untuk penghasilan gris adalah dengan menggunakan sabun natrium, ia adalah kerana natrium merupakan sabun pengental yang terbaik dikalangan tiga jenis sabun pengental tersebut.

CHAPTER 1

INTRODUCTION

1.1 Introduction

Grease is a semi fluid to solid mixture of a fluid lubricant, a thickener, and additives. The fluid lubricant that performs the actual lubrication can be petroleum (mineral) oil, synthetic oil, or vegetable oil. The thickener gives grease its characteristic consistency and holds the oil in place. Common thickeners are soaps and organic or inorganic non soap thickeners.

Soaps are the most common emulsifying agent used, and the type of soap depends on the conditions in which the grease is to be used. Different soaps provide differing levels of temperature resistance (relating to both viscosity and volatility), water resistance, and chemical reactivity. Powdered solids may also be used, such as clay, which was used to emulsify early greases and is still used in some inexpensive, low performance greases.

The majority of greases on the market are composed of mineral oil blended with a soap thickener. Additives enhance performance and protect the grease and lubricated surfaces. Grease has been described as a temperature-regulated feeding device, when the lubricant film between wearing surfaces thins, the resulting heat softens the adjacent grease, which expands and releases oil to restore film thickness.

Greases are employed where heavy pressures exist, where oil drip from the bearings is undesirable, and/or where the motions of the contacting surfaces are discontinuous so that it is difficult to maintain a separating lubricant film in the bearing. Grease-lubricated bearings have greater frictional characteristics at the beginning of operation. Under shear, the viscosity drops to give the effect of an oil-lubricated bearing of approximately the same viscosity as the base oil used in the grease.

1.2 Problem Statement

Grease is a mixture from a fluid lubricant (usually petroleum oil) and thickener (soap). Nowadays the petroleum price has increased each year, one of the factors because of the decreasing of oil reserve and the increasing of demand. Because of the increasing of raw material price, we need to find the solution to produce grease at a low cost.

Nowadays majority of developing countries face water pollution. The major source of water pollution is oil (petroleum and waste lubricants). Most of factories discard their waste into the river and sea. To rectify this situation we propose to recycle the waste to produce grease.

The aim of this research is to find the solution that can reduce the water pollution and at the same time can use the waste to produce grease. This project will benefit not only to the environment, but also the entrepreneur and society.

In this research grease will be produced by using used lubricant oil based on a suitable method. The product will be tested for its viscosity by using a viscometer, to know the quality and the best method to produce grease.

1.3 Objective

Produce grease from used lubricant using different type of soap. Test the performance of the grease by testing viscosity of the product, to define the best type of soap to produce grease.

1.4 Scope

- I. To produce the grease from used lubricant using different type of soap
- II. To define the effect of percent soap to the viscosity of grease
- III. To define the viscosity of the grease using different spindle speed

CHAPTER 2

LITERATURE REVIEW

2.1 Grease Background

Grease is a semi fluid of a fluid lubricant, a thickener, and additives. The fluid lubricant that performs the actual lubrication can be petroleum (mineral) oil, synthetic oil, or vegetable oil. The thickener gives grease its characteristic consistency and is sometimes thought of as a “three-dimensional fibrous network” or “sponge” that holds the oil in place. (John A., 1981)

Common thickeners are soaps and organic or inorganic no soap thickeners. The majority of greases on the market are composed of mineral oil blended with a soap thickener. Additives enhance performance and protect the grease and lubricated surfaces.

Grease has been described as a temperature-regulated feeding device, when the lubricant film between wearing surfaces thins, the resulting heat softens the adjacent grease, which expands and releases oil to restore film thickness.

2.2 Properties

Soap thickeners are formed by reacting a metallic hydroxide, or alkali, with a fat, fatty acid, or ester. The type of soap used depends on the grease properties desired. Calcium (lime) soap greases are highly resistant to water, but unstable at high temperatures. Sodium soap greases are stable at high temperatures, but wash out in moist conditions. Lithium soap greases resist both heat and moisture.

A mixed base soap is a combination of soaps, offering some of the advantages of each type. A complex soap is formed by the reaction of an alkali with a high-molecular weight fat or fatty acid to form soap, and the simultaneous reaction of the alkali with a short-chain organic or inorganic acid to form a metallic salt (the complexing agent). Complexing agents usually increase the dropping of grease.

Lithium, calcium, and sodium greases are common alkalis in complex soap greases (John A, 1981). Non soap thickeners, such as clays, silica gels, carbon black, and various synthetic organic materials are also used in grease manufacture. A multi purpose is designed to provide resistance to heat, as well as water, and may contain additives to increase load-carrying ability and reduce rust.

2.3 Function

The function of grease is to remain in contact with and lubricate moving surfaces without leaking out under gravity or centrifugal action, or be squeezed out under pressure. Its major practical requirement is that it retain its properties under shear at all temperatures that it is subjected to during use.

At the same time, grease must be able to flow into the bearing through grease guns and from spot to spot in the lubricated machinery as needed, but must not add drastically to the power required to operate the machine, mostly at startup. (Boehringer, 1992)

2.3.1 Applications suitable for grease.

Grease and oil are not the same. Grease is used when it is not practical or convenient to use oil. The lubricant choice for a specific application is determined by matching the machinery design and operating conditions with desired lubricant characteristics. Grease is generally used for:

- I. Machinery that runs from time to time or is in storage for an extended period of time. Because grease remains in place, a lubricating film can instantly form.
- II. Machinery that is not easily reached for frequent lubrication. High-quality greases can lubricate isolated or relatively inaccessible components for extended periods of time without frequent replenishing.
- III. Machinery operating under extreme conditions such as high temperatures and pressures, shock loads, or slow speed under heavy load. Under this situation, grease provides thicker film that is required to protect and sufficiently lubricate, whereas oil films can be too thin and can break.

2.3.2 Functional properties of grease.

- I. Functions to minimize leakage and to keep out contaminants. Because of its stability, grease acts to prevent lubricant leakage and also to prevent entrance of corrosive contaminants and strange materials. It also acts to keep seals effective (whereas oil would simply seep away).
- II. Easier to contain than oil. Oil lubrication can require an expensive system of circulating equipment and complex maintenance devices. In comparison, grease is good quality of stiffness, is easily confined with simplified, and less costly maintenance devices.
- III. Holds solid lubricants in suspension. Finely ground solid lubricants, such as molybdenum disulfide and graphite, are mixed with grease in high temperature service (over 315 °C [599 °F]) or in extreme high-pressure applications. Grease holds solids in suspension while solids will settle out of oils.
- IV. Fluid level does not have to be controlled and monitored.

2.3.3 Disadvantages of grease:

- I. Poor cooling. Grease cannot disperse heat by convection like circulating oil.
- II. Resistance to motion. Grease has more resistance to motion at start-up than oil, so it is not appropriate for low torque or high speed operation.
- III. More difficult to handle than oil for dispensing, draining, and refilling. Also, exact amounts of lubricant cannot be as easily metered.

2.4 Grease Characteristics

2.4.1 Apparent viscosity.

At start-up, grease has a resistance to motion, implying a high viscosity. However, as grease is sheared between wearing surfaces and moves faster, its resistance to flow reduces. Its viscosity decreases as the rate of shear increases. By contrast, oil at constant temperature would have the same viscosity at start-up as it has when it is moving. (Boehringer 1992)

To differentiate between the viscosity of oil and grease, the viscosity of grease is referred to as “apparent viscosity.” Apparent viscosity is the viscosity of a grease that holds only for the shear rate and temperature at which the viscosity is determined.

2.4.1.1 Bleeding, migration

Bleeding is a condition when the liquid lubricant separates from the thickener. It is induced by high temperatures and also occurs during long storage periods. Migration is a form of bleeding that occurs when oil in grease migrates out of the thickener network under certain conditions. For example, when grease is pumped through a pipe in a centralized lubrication system, it may encounter a resistance to the flow and form a plug.

The oil continues to flow, migrating out of the thickener network. As the oil separates from the grease, thickener concentration increases, and plugging gets worse. If two different greases are in contact, the oils may migrate from one grease to the other and change the structure of the grease. From (Boehringer 1992)

2.4.1.2. Consistency, penetration, and National Lubricating Grease Institute (NLGI) numbers.

The most important feature of grease is its stiffness or consistency. Grease that is too stiff may not feed into areas requiring lubrication, while grease that is too fluid may leak out. Grease consistency depends on the type and amount of thickener used and the viscosity of its base oil. Grease's consistency is its resistance to deformation by an applied force.

The measure of consistency is called penetration. Penetration depends on whether the consistency has been changed by handling or working. ASTM D 217 and D 1403 methods measure penetration of worked and unworked greases. To measure penetration, a cone of given weight is allowed to sink into a grease for 5 seconds at a standard temperature of 25 °C (77 °F). The depth, in tenths of a millimeter, to which the cone sinks into the grease, is the penetration.

A penetration of 100 would represent solid grease while one of 450 would be semi fluid. The NLGI has established consistency numbers or grade numbers, ranging from 000 to 6, corresponding to specified ranges of penetration numbers. Table 2.1 lists the NLGI grease classifications along with a description of the consistency of each classification. (NLGI lubricant grease guide 4th ed. 28 Feb 99)

Table 2.1: NLGI Grease Classification

NLGI Grease Classification		
NLGI Number	ASTM Worked Penetration 0.1 mm (3.28 × 10 ft) at 25 °C (77° F)	Consistency
000	446-475	Semi fluid
00	400-430	Semi fluid
0	255-385	Very soft
1	310-340	Soft
2	265-285	Common grease
3	220-250	Semi hard
4	175-205	Hard
5	130-160	Very hard
6	85-115	solid

2.4.1.3 Corrosion and rust resistance.

This is the ability of grease to protect metal parts from chemical attack. The natural resistance of grease depends upon the thickener type. Corrosion resistance can be enhanced by corrosion and rust inhibitors.

2.4.1.4 Dropping point.

Dropping point is an indicator of the heat resistance of grease. As grease temperature rises, penetration increases until the grease liquefies and the desired consistency is lost. Dropping point is the temperature at which grease becomes fluid enough to drip. The dropping point indicates the upper temperature limit at which grease retains its structure, not the maximum temperature at which grease may be used. A few greases have the ability to regain their original structure after cooling down from the dropping point.

2.4.1.5 Evaporation.

The mineral oil in grease evaporates at temperatures above 177 °C (350 °F). Excessive oil evaporation causes grease to freeze due to increased thickener concentration. Therefore, higher evaporation rates require more frequent regarding lubrication.

2.4.1.6 Oxidation stability.

This is the ability of grease to resist a chemical union with oxygen. The reaction of grease with oxygen produces insoluble gum, sludge's, and lacquer-like deposits that cause sluggish operation, increased wear, and reduction of clearances. Extended high-temperature exposure accelerates oxidation in greases.

2.4.1.7 High-temperature effects.

High temperatures damage greases more than they damage oils. Grease, by its nature, cannot disperse heat by convection like circulating oil. Therefore, without the ability to transfer away heat, extreme temperatures result in accelerates oxidation or even carbonization where grease hardens or forms a shell. Effective grease lubrication depends on the grease's consistency.

High temperatures bring softening and bleeding, causing grease to flow away from needed areas. The mineral oil in grease can flash, burn, or evaporate at temperatures above 177 °C (350 °F). High temperatures, above 73-79 °C (165-175 °F), can dehydrate certain greases such as calcium soap grease and cause structural breakdown. The higher evaporation and dehydration rates at high temperatures require more frequent grease replacement.

2.4.1.8 Low-temperature effects.

If the temperature of grease is lower enough, it will become so viscous that it can be classified as hard grease. Pump ability and machinery operation may become impossible due to torque limitations and power requirements. The temperature at which this occurs depends on the shape of the lubricated part and the power being supplied to it. As a guideline, the base oil's flow point is considered the low temperature limit of grease.

2.4.1.9 Texture.

Texture is observed when a small sample of grease is pressed between thumb and index finger and slowly drawn apart. Texture can be described as:

- I. Brittle: the grease ruptures or crumbles when compressed.
- II. Buttery: the grease separates in short peaks with no visible fibers.
- III. Long fiber: the grease stretches or strings out into a single bundle of fibers.
- IV. Resilient: the grease can withstand moderate compression without permanent deformation or rupture.
- V. Short fiber: the grease shows short break off with evidence of fibers.
- VI. Stringy: the grease stretches or strings out into long, fine threads, but with no visible evidence of fiber structure.

2.4.1.10. Water resistance.

This is the ability of grease to hold up the effects of water with no change in its ability to lubricate. Soap or water may suspend the oil in the grease, forming a mixture that can wash away or, to a lesser extent, reduce lubricity by diluting and changing grease consistency and texture. Rusting becomes a concern if water is allowed to contact iron or steel components.

2.5 Fluid Lubricants

Fluid lubricants used to formulate grease are normally petroleum or synthetic oils. For petroleum oils in general, naphthenic oils tend to chemically mix better with soaps and additives and form stronger structures than paraffinic oils. Synthetic oils are higher in first cost but are effective in high-temperature and low temperature extremes. With growing environmental concerns, vegetable oils and certain synthetic oils are also being used in applications requiring nontoxic or biodegradable greases. (marcel dekker 1985)

The base oil selected in formulating grease should have the same characteristics as if the equipment is to be lubricated by oil. For instance, lower-viscosity base oils are used for grease applications at lower temperatures or high speeds and light loads, whereas higher-viscosity base oils are used for higher temperatures or low speed and heavy load applications.

2.6 Soap Thickeners

Dispersed in its base fluid, a soap thickener gives grease its physical character. Soap thickeners not only provide consistency to grease, they affect desired properties such as water and heat resistance and pump ability. They can affect the amount of an additive, such as a rust inhibitor, required to obtain a desired quality. The soap influences how a grease will flow, change shape, and age as it is mechanically worked and at temperature extremes. Each soap type brings its own characteristic properties to grease.

The principal ingredients in creating soap are a fatty acid and an alkali. Fatty acids can be derived from animal fat such as beef tallow, lard, butter, fish oil, or from vegetable fat such as olive, castor, soybean, or peanut oils. The most common alkalis used are the hydroxides from earth metals such as aluminum, calcium, lithium, and sodium. Soap is created when a long-carbon-chain fatty acid reacts with the metal hydroxide.

The metal is included into the carbon chain and the resultant compound develops a polarity. The polar molecules form a fibrous network that holds the oil. Thus, a somewhat rigid gel-like material “grease” is developed. Soap concentration can be varied to obtain different grease thicknesses. Furthermore, viscosity of the base oil affects thickness as well. Since soap qualities are also determined by the fatty acid from which the soap is prepared, not all greases made from soaps containing the same metals are identical. The name of the soap thickener refers to the metal (calcium, lithium, etc.) from which the soap is prepared. From (Weiheim Wikey VCH, 2001)

2.7 Additives

An additive that mix together to form grease is as surface protecting and effectively improves the overall performance of grease. Solid lubricants such as molybdenum disulfide and graphite are added to grease in certain applications for high temperatures (above 315 °C or 599° F) and extreme high pressure applications. Incorporating solid additives requires frequent grease changes to prevent accumulation of solids in components.

2.8 Grease Type

2.8.1 Calcium grease.

Calcium or lime grease, the first of the modern production greases, is prepared by reacting mineral oil with fats, fatty acids, a small amount of water, and calcium hydroxide. The water modifies the soap structure to absorb mineral oil. Because of water evaporation, calcium grease is sensitive to elevated temperatures. It dehydrates at temperatures around 79 °C (175° F) at which its structure collapses, resulting in softening and, eventually, phase separation.

Greases with soft consistencies can dehydrate at lower temperatures while greases with firm consistencies can lubricate satisfactorily to temperatures around 93 °C (200 °F). In spite of the temperature limitations, lime grease does not emulsify in water and is excellent at resisting “wash out.” Also, its manufacturing cost is relatively low. If calcium grease is prepared from 12-hydroxystearic acid, the result is hydrous (waterless) grease. Since dehydration is not a concern, anhydrous calcium grease can be used continuously to a maximum temperature of around 110 °C (230 °F).

Calcium complex grease is prepared by adding the salt calcium acetate. The salt provides the grease with extreme pressure characteristics without using an additive. Dropping points greater than 260 °C (500 °F) can be obtained and the maximum usable temperature increases to approximately 177° C (350 °F). With the exception of poor pump ability in high-pressure centralized systems, where caking and hardening sometimes occur calcium complex greases have good all-around characteristics that make them desirable multipurpose greases.

2.8.2 Sodium grease.

Sodium grease was developed for use at higher operating temperatures than the early hydrated calcium greases. Sodium grease can be used at temperatures up to 121 °C (250 °F), but it is soluble in water and readily washes out. Sodium is sometimes mixed with other metal soaps, especially calcium, to improve water resistance. Although it has better adhesive properties than calcium grease, the use of sodium grease is declining due to its lack of flexibility. It cannot compete with water resistant, more heat resistant multipurpose greases. However, it is still recommended for certain heavy duty applications and well sealed electric motors.

2.8.3 Aluminum grease

Aluminum grease is normally clear and has a somewhat stringy texture, more so when produced from high viscosity oils. When heated above 79 °C (175 °F), this stringiness increases and produces a rubberlike substance that pulls away from metal surfaces, reducing lubrication and increasing power consumption. Aluminum grease has good water resistance, good adhesive properties, and inhibits rust without additives, but it tends to be short-lived. It has excellent inherent oxidation stability but relatively poor shear stability and pumpability.

Aluminum complex grease has a maximum usable temperature of almost 100 °C (212 °F) higher than aluminum soap greases. It has good water and chemical resistance but tends to have shorter life in high temperature, high speed applications.

2.9 Compatibility

Greases are considered incompatible when the physical or performance characteristics of the mixed grease fall below original specifications. In general, greases with different chemical compositions should not be mixed. Mixing greases of different thickeners can form a mix that is too firm to provide sufficient lubrication or more commonly, a mix that is too soft to stay in place.

Combining greases of different base oils can produce a fluid component that will not provide a continuous lubrication film. Additives can be diluted when greases with different additives are mixed. Mixed greases may become less resistant to heat or have lower shear stability. If a new brand of grease must be introduced, the component part should be disassembled and thoroughly cleaned to remove all of the old grease. If this is not practical, the new grease should be injected until all traces of the prior product are flushed out. Also, the first grease changes should be more frequent than normally scheduled.

2.10 Grease Application Guide

When selecting grease, it is important to determine the properties required for the particular application and match them to specific grease. A grease application guide is shown in Table 2.2. It shows the most common greases, their usual properties, and important uses. Some of the ratings given are subjective and can vary significantly from supplier to supplier. Common ASTM tests for the grease characteristics describe are shown in Table 2.3.

Table 2.2: Grease Application Guide

Grease Application Guide (Boehringer, 1992)								
Properties	Aluminum	Sodium	Calcium-Conventional	Calcium - Anhydrous	Lithium	Aluminum Complex	Calcium Complex	Lithium Complex
Dropping point (EC)	110	163-177	096-104	135-143	177-204	260+	260+	260+

CHAPTER 3

METHODOLOGY

3.1 Introduction

This chapter explains conceptual study, laboratory experimental work, analyzing and completion of the project. The detailed procedure of the experimental work is discussed throughout this chapter. In general, the experiment consists of two major section, laboratory work (production grease) and data analysis.

3.2 Overall Methodology

The experiments were carried out according to the standard procedure outline in section 3.3. The experiments were divided into two parts. The first part was to prepare the samples of grease by using used lubricant as base oil instead of petroleum oil. The second part of the experiment involved analyzing the product by determines the viscosity of the grease using viscometer. Figure 3.1 shows the outline of the overall methodology where Experiment Work 1 was producing grease from used lubricant, 3 different type of soap is used in this experiment. For the Experiment Work 2 where the product dropping point and viscosity was analyzed. Then the comprehensive discussion

was carried out on the viscosity of the grease, to know and analyzed the quality of the grease product.

3.3 Experimental Methodology

3.3.1 Production of Grease

Used lubricant were collect from mechanical lab, used lubricant is a major component to produce grease. Used lubricant is base oil for production grease instead of petroleum oil. For production grease, soap is used as a thickener for the base oil. Three major type of thickener is used, calcium soap, sodium soap and aluminum soap. Metallic hydroxides were mixed with fatty acid (cooking oil) with ration 15% and 85% by mass at the room temperature. Four different soap ratios is used, which is 10%, 20%, 30% and 40% by volume mixed with base oil for each of soap. Base oil and soap (thickener) mixture were heated up to 200°C using the rotary evaporator bath. At the same time the mixture were stir to improve the mixing efficiency. The mixture was heated for 1½ hour then is cooling down to get the product.

3.3.2 Analysis Using Viscometer (Brookfield DV-III Ultra Programmable Rheometer)

The Brookfield DV-III ultra programmable rheometer measure fluids and semi fluids parameters of shear stress and viscosity at given shear rates. Viscosity is a measure of a fluids and semi fluid to flow. The principle of operating of the DV-III Ultra is to drive a spindle (which is immersed in the test fluid) through a calibrated spring. The viscous drag of the fluid against the spindle is measured by the spring deflection. Spring deflection is measured with a rotary transducer. The viscosity measurement range of the DV-III Ultra (in centipoises or CP) is determined by the rotational speed of the spindle, the size and shape of the spindle, the container the spindle is rotating in, and the full scale torque of the calibrated spring.

Viscosity is the measure of the internal friction of a fluid. This friction becomes apparent when a layer of fluids is made to move in relation to another layer. The greater the friction, the greater the amount of force required to cause this movement, which is called 'shear'. Shearing occurs whenever the fluid is physically moved or distributed, as in pouring, spreading, spraying, mixing. Highly viscous fluids, therefore, required more force to move than less viscous material.

3.3.2.1 Rheometer

Rheometer is equipment use to measure viscosity. It is advancement in viscosity measurement which can be connected with PC and available with software. This instrument, with variable speed capability, allows easy handling and programming of complication measurement.
